ABSTRACT
Nanosuspensions are colloidal dispersions and biphasic system consisting of drug particles dispersed in an aqueous vehicle in which the diameter of the suspended particle is less than 1μm in size. Many drugs including antibiotics are having poor solubility. Nanosuspensions have proven to be a better alternative over other approaches currently available for improving bioavailability of such drugs with low solubility. This review describes the methods of pharmaceutical nanosuspension of antibiotic formulations and pharmaceutical applications in drug delivery.

Keywords: Nanosuspension, Bioavailability, Solubility

INTRODUCTION
Nanotechnology is likely to make a big change in our lives, in general, and health scenario, in particular. It is one of the most important research and development area in today’s era. Nanotechnology is an applicable aspect of a broader area of nanoscience which is one of the upcoming and highly challenging as well as rewarding key research area in the modern scientific set up [1]. It is the science of small particle having unique properties, which change on altering the size of the particle [2]. Nanosuspensions are colloidal dispersions and biphasic system consisting of drug particles dispersed in an aqueous vehicle in which the diameter of the suspended particle is less than 1μm in size. Reduction of drug particles to nanometer range leads to an enhanced dissolution rate due to increased surface area and saturation solubility [3]. A nanosuspension not only solves the problem of poor solubility and bioavailability but also alters the pharmacokinetics of drug and improves the drug safety and efficacy. Nanosuspension has been reported to enhance absorption and bioavailability.

IMPORANCE OF ANTIBIOTICS AS NANOSUSPENSION
Antibiotics also called anti-bacterial are a type of antimicrobial drug used in the treatment and prevention of bacterial infections. They may either kill or inhibit the growth of bacteria. Many antibiotics such as Ciprofloxacin, Sulfadiazine, belong to BCS class II/IV, having poor solubility and dissolution rate. Nanoizing of such drugs leads to a drastic increase in their oral absorption and consequently bioavailability. The increase in bioavailability is due to increased surface area of the particles, increased saturation solubility and increase in dissolution velocity. The drug dose reduction is possible with enhancement in bioavailability making therapy cost effective and in preventing toxicity [4]. Formation of nanoparticles could provide some benefits such as increased saturation solubility and drug dissolution rate, improved bioavailability and dose proportionality, and inter-subject variability in comparison with the coarse or micronized drug powder [5].
METHODS OF PREPARATION6-13

Preparation of nanosuspension is reported to be simpler and cost effective. It is particularly for poorly soluble drugs and to yield a physically more stable product. For manufacturing nanosuspensions, there are two methods, “Top-down process technology” and “Bottom-up process technology”.

The top-down process includes:-
- High pressure homogenization
- Media milling (Nanocrystals).

Bottom-up process includes:-
- Solvent- Antisolvent method
- Super critical fluid process
- Emulsification Solvent evaporation technique
- Lipid emulsion/Micro-emulsion template.

The principle techniques used in recent years for preparing nanosuspensions are:

1. High pressure homogenization:

   It is most widely used method for preparing nanosuspensions of many poorly aqueous soluble drugs. It involves three steps. First, the drug powders are dispersed in stabilizer solution to form pre-suspension, and then the pre-suspension is homogenized in high pressure homogenizer at a low pressure for pre-milling, and finally homogenized at high pressure for 10 to 25 cycles until the nanosuspensions of desired size are formed.

2. Milling techniques:

   a) Media Milling:

   This method was first developed and reported by Liversidge (1992). The nanosuspensions by this method are prepared by high shear media mill. The milling chamber is charged with the milling media, water, drug and stabilizer and rotated at a very high shear rate under controlled temperature for at least 2-7 days. The milling medium is composed of glass, Zirconium oxide or highly cross linked polystyrene resin. The high energy shear forces are formed as a result of impaction of milling media with the drug which results in breaking of drug microparticles to nanosized particles.

   b) Dry-Co-grinding:

   Recently many nanosuspensions are prepared by dry milling technique. Dry-co-grinding can be carried out easily and economically and can be conducted without organic solvents. Physicochemical properties and dissolution of poorly water soluble drugs are improved by Co-grinding because of the improvement in the surface polarity and transformation from a crystalline to an amorphous drug.

3. Emulsification-solvent evaporation technique

   This technique involves preparing a solution of drug followed by its emulsification in another liquid that is a nonsolvent for the drug. Evaporation of the solvent leads to precipitation of the drug. Crystal growth and particle aggregation can be controlled by creating high shear forces using a high-speed stirrer.

4. Precipitation method

   Within the last decade, precipitation has been applied to prepare submicron particles, especially for the poorly soluble drugs. The drug is first dissolved in a solvent, then this solution is mixed with a miscible anti-solvent in the presence of surfactants. Rapid addition of a drug solution to the anti-solvent leads to sudden super saturation of drug and formation of ultrafine crystalline or amorphous drug solids.

5. Supercritical fluid process

   The particle size reduction was achieved more by the solubilisation and nanosizing technologies through the super critical fluid process. Super critical fluids (SCF) are non-condensable dense fluids whose temperature and pressure are greater than its critical temperature (Tc) and critical pressure (Tp). This process allows the micronization of drug particles to a submicron level. Recent advances in SCF process are to create nanoparticulate suspension of particle size of 5 to 200nm in diameter.

6. Melt emulsification method

   In this method drug is dispersed in the aqueous solution of stabilizer and heated above the melting point of the drug and homogenized to give an emulsion. During this process, the sample holder will be wrapped with a heating tape fitted with temperature controller and the temperature of emulsion will be maintained above the melting point of the drug. The emulsion is then cooled down either slowly to room temperature or in an ice-bath.

7. Lipid emulsion/microemulsion template:

   This method is mostly applicable for drugs that are soluble in either volatile organic solvents or partially water miscible solvents. In this method, the drug is dissolved in suitable organic solvent and then emulsified in an aqueous phase using suitable surfactants. Then the organic solvent is slowly evaporated under reduced pressure to form drug particles precipitating in the aqueous phase forming the aqueous suspension of the drug in the required particle size. Then the suspension formed can be suitably diluted to get nanosuspensions. Moreover, microemulsions as templates can produce nanosuspensions. Microemulsions are thermodynamically stable and isotropically clear dispersions of two immiscible liquids such as oil and water stabilized by an interfacial film of surfactant and co-surfactant. The drug can be either loaded into the internal phase or the pre-formed microemulsion can be saturated with the drug by intimate mixing. Suitable dilution of the microemulsion yields the drug nanosuspension.

8. Solvent evaporation:

   In the solvent evaporation method, the solutions of polymer are prepared in volatile solvents and emulsions. The emulsion is converted into a nanoparticle suspension on evaporation of the solvent for the polymer, which is allowed to diffuse through the continuous phase of the emulsion. In the conventional methods, two main strategies are being used for the formation of emulsions, the preparation of single-
emulsions, e.g., oil-in-water (o/w) or double-emulsions, e.g., (water-in-oil)-in-water, (w/o)/w. These methods require high-speed homogenization or ultrasonication, followed by evaporation of the solvent, either by continuous magnetic stirring at room temperature or under reduced pressure. By ultracentrifugation the solidified nanoparticles are collected which is washed with distilled water to remove the additives like surfactants, and then it is lyophilized. The particle size is influenced by the concentration of polymer, stabilizer and the speed of homogenizer.

APPLICATIONS<sup>32-34</sup>

- **Oral administration**

Nanosizing of drugs leads to an increased oral absorption and subsequent bioavailability. Improved bioavailability is due to the adhesiveness of drug nanoparticles to the mucosa and the increased saturation solubility leading to an increased concentration gradient between gastrointestinal tract lumen and blood. Aqueous nanosuspensions can be used directly in a liquid dosage form and a dry dosage form such as tablet or hard gelatin capsule with pellets. Granulates can also be produced by spray drying of nanosuspensions.

- **Ophthalmic drug delivery**

Nanosuspensions have been providing to be vital for drugs that exhibit poor solubility in lachrymal fluids. Suspensions offer advantages such as prolonged residence time, which is desirable for most ocular diseases for effective treatment and avoidance of high toxicity created by water soluble drugs. Their actual performance depends on the intrinsic solubility of the drug in lachrymal fluids. Thus the intrinsic dissolution rate of the drug in lachrymal fluids governs its release and ocular bioavailability.

- **Intravenous administration**

Parenteral route of administration provides a quick onset of action, rapid targeting and reduced dosage of the drug. It is the preferred route for drugs undergoing first-pass metabolism and those that are not absorbed in the GIT or that get degraded in the GIT. One of the important applications of nanosuspension technology is the formulation of intravenously administered products. IV administration results in several advantages, such as administration of poorly soluble drugs without using a higher concentration of toxic cosolvents, improving the therapeutic effect of the drug available as conventional oral formulations and targeting the drug to macrophages and the pathogenic microorganisms residing in the macrophages.

- **Targeted drug delivery**

Nanosuspensions can also be used for targeted delivery as their surface properties and in vivo behaviour can easily be altered by changing either the stabilizer or the milieu. Their versatility, ease of scale up and commercial product has helped in developing commercial viable nanosuspensions for targeted delivery.

- **Pulmonary administration**

Aqueous nanosuspensions can be nebulized using mechanical or ultrasonic nebulizers for delivery of the drug into lungs. Because of their small size, it is likely that in each aerosol droplet at least one drug particle is contained, leading to a more uniform distribution of the drug in lungs. They also increase adhesiveness and thus cause a prolonged residence time. Budesonide drug nanoparticles were successfully nebulized using an ultrasonic nebulizer.

- **Mucoadhesion of the nanoparticles**

Nanoparticles orally administered in the form of a suspension diffuse into the liquid media and rapidly encounter the mucosal surface. The particles are immobilized at the intestinal surface by an adhesion mechanism referred to as "bioadhesion". Then, the concentrated suspension acts as a reservoir of particles and an adsorption process takes place rapidly. The direct contact of the particles with the intestinal cells through a bioadhesive phase is the first step before particle absorption. The adhesiveness of the nanosuspensions not
only helps to improve bioavailability but also improves targeting of the parasites persisting in the GIT.

CONCLUSION

The nanosuspension technology have been successfully proved to be useful for overcoming problem associated with poorly soluble drugs or lipophilic drugs insoluble in both organic and aqueous media. Large scale production of nanosuspension can be employed by media milling and high pressure homogenization technique. The recent advancement in the work being done related to nanosuspension shows that many formulations are being developed on a laboratory scale which have a potentially important clinical significant to treat diseases. Thus, nanosuspension technology is able enough to bring enormous immediate benefits and will revolutionize the research and practice of medicine in the field of pharmacy.
