ABSTRACT

Objective: To deliver bioadhesive buccal films of artemether (ART) with ability to adhere, hydrate and release drug across the buccal membrane. **Methods:** Buccal films prepared by film casting using carrageenan (CAR) and *Prosopis africana* (PRO) were characterized by size, zeta potential, texture, water content, morphology, thermal and interaction studies, *in vitro* and *in vivo* antiparasmodial activity in mice. **Results:** Films were stable with sizes (2442 and 835 nm), water content (21 and 15 %), bioadhesivity (24 and 9.4 %) and film thickness (0.18 and 0.28 mm) for CARART and PROART respectively. Enthalpy of CARART, PROART and ART were 76, 22 and 88 J/g where as parasitaemia reduction of 67 and 76 % were observed for CARART and PROART respectively. **Conclusion:** Though CARART had better water content and bioadhesivity necessary for film hydration at buccal membrane, PROART eventually had superior buccal performance perhaps due to its film thickness and amorphous nanoparticle subdivision.

Key words: Artemether; Carrageenan; *Prosopis africana*; Sublingual buccal films; Malaria

Anthony A. Attama: Co-supervised this work and proof-read the manuscript.

1. INTRODUCTION

There has been a paradigm shift from conventional drug delivery systems (injections and orals) to alternative systems based on versatile novel drug delivery systems (NDDS) ¹⁻⁴. NDDS are capable of delivering drugs through mainly non-invasive routes with the aim to improve use convenience and compliance⁵. These systems exploit the mucosal surfaces of skin, nose and oral cavities while delivering drugs through different carrier systems⁶. By implication, delivery systems such as topicals (gels, films, patches, creams etc), aerosols and other transdermal DDS not limited to the oral cavity (sublingual, oesophageal, and buccal systems) apply. Buccal delivery systems (BDS) may include disks, tablets, patches, liquids and semi-solids⁷⁻¹⁰ but among all, films and/or patches have shown greater preference⁸⁻¹¹. These systems generally need to be bio- and/or muco-adhesive to be able to withstand some obvious stresses due to their application sites, to be able to provide both local and/or systemic effects. For instance, due to the flushing action of saliva and/or food ingestion, BDS may suffer from frequent dosing, non-uniform absorption as well as dislodgement by the tongue^{10, 12}. Drug ionization could also occur for ionizable drugs due to pH of microenvironment thereby making the route impracticable for drugs with low pKa values since pH of the saliva is 6.5-6.9^{13, 14}. Therefore, to increase BDS residence contact time on mucosal membranes, hydrogel polymers (having numerous hydrogen bonding groups) could be used to provide bioadhesivity and flexibility^{11, 14}. This would predispose BDS to proffer numerous advantages such as to bypass liver metabolism, avoid gastric irritation and enzymatic degradation in the gastrointestinal tract (GIT), provide local specificity and above all, improve use convenience and compliance¹⁵⁻¹⁷. Hence different local conditions of the oral cavity could easily be treated with BDS including oral ulcers, oral infections, dental caries, periodontitis, gingivitis etc¹⁴, as well as systemic administration of macromolecular agents such as peptides, proteins, and polysaccharides^{4, 11}.

Prosopis africana (PRO) polymer is obtained from the tropical plant *Prosopis africana*. Similar to k-carrageenan (CAR), PRO is a generally regarded as safe (GRAS) polymer for different uses including extended release polymer¹⁸, bio/muco-adhesive systems^{19, 20}; solubility enhancer²¹, plasticizer²¹, binder for tablets²², film/patches^{21, 23}, food supplement²⁴⁻²⁶, antimicrobial²⁷, and water treatment²⁸ etc. *Prosopis* gum is a natural polysaccharide consisting chiefly of glucose, fructose, galactose and xylose as the monosaccharide units, as determined by thin layer chromatography and complete acid hydrolysis analysis^{19, 29}. The gum is made up of highly branched polysaccharides with chain structure formed when monosaccharides condense with the elimination of water molecule(s)¹⁹. The structural components of its rich amino acid constituents have been implicated in solubility enhancement properties through abundant hydrogen bonding groups²¹. It is a well-known biodegradable and biocompatible bioadhesive agent due to its anionic nature which aids more effective mucosal and/or tissue binding¹⁸⁻²⁰. Additionally, it is a sought-after food condiment for the Nigerian people due to its low toxicity. In the light of its bioadhesivity, low toxicity and cheap availability, it can be proposed as a delivery system for developing effective buccal adhesive films for treatment of some tropical disease such as malaria.

The antimalarial drug, artemether (ART) is a fast acting schizonticidal drug and the most effective of the artemisinin-combination therapies (ACT) for first-line treatment of malaria³⁰. The challenge of drug resistance by *Plasmodium* parasite makes a short acting drug such as ART

not to be useful as a monotherapy as conventionally obtainable, example in the capsule form (80-160 mg daily for 5 days)²¹. Instead, the fast-acting derivatives of artemisinin (artemether, dihydroartemisinin, arteether and artesunate) are combined with long acting antimalarials (lumenfantrine, amodiaquine, sulfadoxin-pyrimethamine, mefloquine, piperazine) as ACTs, to deal with fast resolution of clinical symptoms as well as recrudescence³¹. Among all ACTs, artemether-lumenfantrine is the most widely used in different fixed oral (tablets) combinations (80/480, 40/240 and 20/120 mg) for treatment of uncomplicated falciparum malaria including multi-drug resistant ones^{21, 31}. The large oral doses have attendant associated side effects (especially neurotoxicity) following twice daily dosing and rapid but incomplete absorption after oral administration with peak plasma concentrations reached about 2 h in addition to metabolism in the liver to the demethylated derivative, dihydroartemisinin (DHA)²¹. More so, it is rapidly eliminated with oral bioavailability after intramuscular injection approx. 43%. Therefore, ART administration via the oral mucosa (buccal and sublingual) seems attractive due to its short action which could resolve its hepatic first-pass metabolism and degradation in the gastrointestinal tract, GIT^{14, 32}. This is hoped to exploit the rich blood supply (20.3 mL/min/100 g tissue) available in the oral mucosa, the high surface area (50.2 cm²) as well as thin membrane (low thickness) 500-600 μ m therein, to generally increase ART uptake^{14, 33}.

In the light of the above, we report here the development of solvent cast films for buccal delivery of artemether (ART). These drug films were produced with k-Carrageenan (CAR) and *Prosopis africana* (PRO) as hydrogel polymers with the aid of propylene glycol (plasticizer), saccharine sodium (sweetener) and peppermint oil (flavourant); following optimizations of concentration (plasticizer, polymer, sweetener and flavor), drying time, temperature and functional properties of the final films. The resultant drug films (CARART and PROART) were characterized by thickness, drug content, folding endurance, morphology, weight variation, viscosity, degree of crystallinity and compatibility, *in vitro* drug release, *ex vivo* bioadhesivity and *in vivo* growth inhibition of plasmodium in malariogenic mice. To understand the particle make-up, carefully measured film size (2 cm²) was allowed to swell for 8 h in milliQ-water (5 ml) of pH 6.8 and the aqueous dispersion was checked for size (Z-ave), polydispersity index and zeta potential. All these were done to provide proof as to hope for effective BDS of ART which could improve use convenience and compliance to reduce development of resistance as well as an alternative low dose regimen to oral large-dosed tablets.

2. MATERIALS AND METHODS

2.1. Materials

Artemether was a gift from Ipca Laboratories Ltd. India. Other ingredients include k-carrageenan and absolute ethanol, (Sigma Aldrich, Germany), propylene glycol, sodium saccharine and peppermint oil (Merck, Germany). All other reagents and solvents were analytical grade and were used as procured.

2.2. Preparation of Prosopis polymer

Prosopis seed was procured from Orba market, Udenu Local Government Area of Enugu State, Nigeria. *Prosopis africana* peel powder (PAPP) was prepared according to earlier methods^{18, 28, 34}, with slight modifications. Briefly, *Prosopis* seeds were boiled overnight. After the inner fermentable seed (soup flavorant in Nigeria) was separated from the peels, there was further separation

of the peel into two parts: 1) fleshy white mesocarp (gum containing portion) and, 2) hard pericarp (outermost part). The white mesocarp (gum) was washed (thrice) with deionized water, sun-dried to constant weight and ground into powder using laboratory grinding machine. The powder was sieved with a laboratory sieve of known mesh size to obtain fine powders used for this study.

2.3. Formulation of films

Prior to final preparations, all parameters including concentration (polymer, drug, plasticizer, sweetener and flavorant), stirring time and drying temperature were optimized. To determine the optimal drying time, equal amount of dispersion was poured into Petri dishes (diameter 3.4 cm²) and weighed every 24 h up to 72 h until a constant weight was achieved. An impermeable backing membrane/layer was prepared from ethanol (E), ethylcellulose (EC) and soy bean oil (SBO) to represent 4 and 10 %w/v respectively of SBO and EC in absolute E. The mixture was stirred until homogeneous solution was obtained. This solution (10 ml) was poured into Petri dish (3.4 cm) and dried in the oven at 30 °C for 3 h.

Aqueous solution of polymers (k-carrageenan (CAR) and *Prosopis* polymer (PRO)) were prepared by separately adding 1 g of CAR or PRO to 25 ml of distilled water and stirring for 5 min. Some 10 mg of saccharine sodium (sweetener) was added to solution and stirred for 5 min, before addition of propylene glycol (10 ml) as plasticizer and stirring for another 1 min³⁵. This was followed by the addition of 1 ml of peppermint oil (flavourant) and final stirring for further 1 min to give solution A. For the blank films (without drug), the resultant solution A was cast into Petri dishes (diameter 3.4 cm) containing the dried backing layers and covered with an inverted funnel for gradual drying at room temperature. For the drug-containing films, optimized concentration of 500 mg of artemether (ART) was added into 5 ml of absolute ethanol and stirred for 5 min to give solution B. Solution A was separately added into solutions B and mixtures were stirred for 10 min before casting as earlier described. Triplicate formulations were made for each batch. After drying at room temperature, the films were stored in desiccators until used. Artemether films formulated with carrageenan were coded as CARART while those formulated with *Prosopis africana* were referred to as PROART.

2.4. Physical evaluation of hydrogels

Prior to casting, the hydrogel formulations were physically examined for color, homogeneity, and consistency. The pH was also re-evaluated (before each use) to make sure that it was stable within the salivary pH of 6.5-6.9.

2.5. Morphology and texture analysis

The morphology of the film samples was analyzed through scanning electron microscopy (SEM). The dry films were gold coated to about 5 µm thickness using a coater unit under a high vacuum. SEM analysis of films (PROART and CARART) was performed on a Philips XL-30M scanning electron microscope instrument.

2.6. Microenvironment pH and particle characterization

The microenvironment pH of carefully measured film sizes (2 cm²) were determined to evaluate possible oral mucosal irritation. The films were allowed to swell for 8 h in milliQ-water of pH 6.8 contained in small beakers. The pH of the aqueous dispersion was determined using a pH meter

(L1 127 Elico, India). Triplicate measurements were done per batch of formulation.

The mean diameter (Z-ave) and polydispersity index of the above aqueous dispersions obtained from CARART and PROART films were measured after appropriate dilutions using a Zetasizer Nano-ZS (Malvern Instruments, Worcester, UK) equipped with a 10 mW He-Ne laser employing the wavelength of 633 nm and a backscattering angle of 173 ° at 25 °C. All samples were diluted with sufficient milliQ-water to obtain a suitable scattering intensity, before photon correlation spectroscopic (PCS) analysis, and were then placed in a 10 mm diameter cell. Particle size analysis was performed using Mie theory.

The zeta potentials of the drug films were determined via electrophoretic mobility measurements using a Zetasizer Nano-ZS (Malvern Instruments, Worceshire, UK). The zeta potential was calculated applying the Helmholtz-Smoluchowski equation ($n = 3$).

2.7. Technological evaluation of the films

The thickness of the film was measured with micrometer screw gauge (Mitutoyo, Kawasaki Japan). The measurement was taken at five different areas of the film; four around the edges and one in the center. The mean and standard deviation of the five measurements was calculated for each film. For weight variation, ten films from each of CARART and PROART batches were individually weighed. Variations in weight were determined after triplicate determination. The Folding endurance (FE) of the formulated films were determined by repeatedly folding the films of uniform cross-sectional area (4x4 cm²) and thickness, at the same place until it broke. The number of times each film was folded at the same place without breaking gave the value of FE. Triplicate determinations were done for validity of statistical result.

2.8. Bioadhesive evaluation of the films

The bioadhesive property of the formulated films were determined using a texture analyzer (TA.XT2, Stable Micro System, UK) and fresh chicken pouch as a model tissue as previously described³⁶ with slight modification. The calculated work of adhesion was used as a measure of the bioadhesive property of the films.

2.9. Differential scanning calorimeter (DSC)

DSC experiments (TA Instrument, USA) were performed to detect the phase transition of the pure compounds and their mixtures as well as investigate any possible interaction between the initial compounds used to prepare the films. To investigate the transition of drug molecule from crystalline to amorphous form during the formulation process, sufficient quantity of PROART and CARART films enough to contain at least 3–5 mg of ART was weighed in aluminum pans, heated from 25 to 150 °C at 10 °C/min under constant flushing with nitrogen (10 ml/min). The DSC parameters, such as temperature onset, maximum peak, and enthalpy were generated.

2.10. Fourier transform infrared spectroscopy (FT-IR)

FT-IR study was carried out using BIO-RAD FT-IR 3000 (BIORAD Company, USA). The FT-IR spectra of PROART and CARART buccal films, ART, PRO and CAR polymers were obtained using KBr discs in the region of 4000–500 cm⁻¹.

2.11. Thermogravimetric analysis (TGA)

TGA was used to measure the water content within the film. Samples weighing between 3 and 10 mg were packed into aluminum pan and placed in a tarred balance of a high-

resolution TG 2950 instrument (Crawley, UK). The TGA was programmed to heat the sample from 25 to 150 °C at the rate of 10 °C/min. The weight loss was noted and used to calculate the water content of the films.

2.12. Drug content analysis

Accurately weighed 100 mg of drug film (CARART and/or PROART) was transferred to a 100 ml volumetric flask and dissolved with 5 ml of ethanol. To it, 25 ml of 1N HCl was added and heated using thermo-regulated water bath for 30 min at temperature of 80 ± 2 °C, slightly modified according to an earlier method³⁷. The solution was allowed to cool at room temperature, filtered and the volume was made up to 100 ml mark with deionized water and/or simulated salivary fluid, SSF (pH 6.5). This was scanned in a UV/VIS spectrophotometer (Spectrumlab 752s, UK) at 254 nm and the amount of drug was calculated reference to a Beer's plot.

2.13. Dissolution rate studies and drug release kinetics

Drug dissolution studies were determined using magnetic stirrer method. Some 50 ml of two different dissolution media (deionized water and SSF, pH 6.5) contained in beakers were placed on magnetic stirrer hot plate at 37 °C with stirring speed of 100 rpm. A volume of 5 ml was withdrawn at initial 30 min interval then at hourly interval for 12 h while replacing each withdrawal with 5ml of fresh media. However, to each 5ml withdrawn sample at different time intervals, 0.5 ml of ethanol and 2.5 ml of 1N HCl were added and heated for 25 min in a water bath at 80 ± 2 °C, cooled, filtered and diluted to 10 ml with the medium before UV/VIS measurement (Spectrumlab 752s, UK) at 254 nm.

Different release models³⁷ were applied to study the kinetics and mechanisms of ART release from mucoadhesive films including zero order, first order, Higuchi and Korsmeyer-Peppas models. First order assessed log cumulative of % drug remaining versus time whereas zero order was done by fitting cumulative % drug release versus time³⁸. The cumulative % drug release versus square root of time described Higuchi model, whereas Ritger-Peppas and Korsmeyer-Peppas models assessed both Fickian and non-Fickian release of drug from swelling as well as non-swelling systems by $\text{Log } (M_t / M_\infty) = \text{Log } k + n \text{ Log } t$. The best fit model depended on the linearity of the plots as represented by the R^2 values³⁷.

2.14. Ex vivo buccoadhesivity of films on bovine buccal membrane

Bovine buccal mucosa was collected from freshly slaughtered cow from Ogige market abattoir, Nsukka (Nigeria) and frozen until used. The mucin lining of the buccal membrane was gently scraped off with spatula leaving a thin membrane which was spread on Teflon block and wrapped with aluminum foil before storing in the

freezer. Prior to use, it was thawed in saline solution at ambient temperature.

The biological membrane was fixed on a non-absorbable surface then pinned with dissecting pins to prevent the tissue from slipping off. The film was attached to the ring of the Du Nouy tensiometer with cyanoacrylate adhesive and lowered to make contact (5 min) with the tissue membrane on the platform³⁹. The ring with the film was gradually raised at the rate of 1 mm/min. The force (g) was taken at equal intervals until the film was completely detached from the tissue membrane. Film contact time with the intestine was 5 min in each determination and a curve was traced between contact time (min) and force (g) whereby the work of adhesion (g/cm) was equal to the area under the curve. Triplicate determinations were taken for each film batch.

2.15. In vivo schizontocidal activity

The animal experimental protocols were in accordance with the guidelines for conducting animal experiments stipulated by our Institution's Animal Ethics Committee⁴⁰ and in compliance with the Federation of European Laboratory Animal Science Association and the European Community Council Directive of November 24, 1986 (86/609/EEC). Briefly, the mice were divided into four groups of five mice each.

Evaluation of the curative effect of formulated films against established plasmodium infection was carried out³⁷. On the day 0 of the test, percentage parasitemia and red blood cell count of the donor mice was determined by a Giemsa-stained thin blood smear of the donor mice and improved Neubauer counting chamber respectively. Blood of the donor mice was collected by cardiac puncture and diluted with physiological saline (normal saline) to 10^8 parasitized erythrocytes per ml (i. e. 0.2 ml of 10^8 parasitized erythrocyte/ml), which was injected intra-peritoneally into each of the experimental mice in Fig. 1 (image A, B). Thirty mice were all inoculated with chloroquine-sensitive strain of *Plasmodium berghei berghei* (NK 65) and left untreated until the fourth day (D_4) post inoculation. The mice were weighed and randomized into six groups of five mice each. Post inoculation (day 4), Group A (negative control) was administered with 1 ml/kg of distilled water, group B (positive control) received 5 mg/kg body weight equivalent to 12.5 mg of ART oral tablet dispersed in 1 ml of distilled water. Groups C and D received uniform doses of ART (5 mg) contained in drug film of CARART (11.4 mg) and PROART (12.4 mg) which were carefully stocked to the palates of the mice (image C). On day-7 (D_7), each mouse was tail-bled (image D) and a thin blood film was made on a microscope slide. The films were stained with 10% Giemsa solution and examined microscopically to monitor the parasitaemia level. The antimalarial activity was determined by the equation:

$$\% \text{ Activity} = \frac{\text{Mean parasitaemia in treated group}}{\text{Mean parasitaemia in control group}} \times 100 \quad (1)$$

Fig. 1: Preparation and treatment of malariogenic mice

2.16. Statistical analysis

All the data generated were expressed as mean $\pm$ standard deviation. For group comparisons, one-way ANOVA with duplication was applied. Statistical significance was determined using student t-test, with $P < 0.05$ considered to be statistically significant.

3. RESULTS

3.1. Physical evaluation of hydrogels

To increase residence, contact time of the films on mucosal membranes, hydrogel polymers (PRO and CAR), having numerous hydrogen bonding groups were used to provide bioadhesivity and flexibility^{11, 14}. The PROART hydrogel formulated was homogenous, partially transparent and fairly viscous, while the PROART film was moderately transparent. The CARART hydrogel was homogenous, transparent and less viscous than PROART, while the CARART film was very transparent. CARART films were therefore lighter than PROART films as well as had more uniform measurements. Hydrogel particles were spherical but not so in dry films.

3.2. Morphology and texture analysis

Scanning electron microscopic (SEM) analysis was adopted to investigate the surface characteristics and internal structure of the formulated artemether-loaded films (CARART and PROART). Single particles of the polymers CAR (A-C), PRO (J-L) and ART (M-O) in (Fig. 2) appeared more cuboid while ART-films CARART (D-F) and PROART (G-I) were of different shapes. The shape of drug carriers have been reported to be dependent on the purity of the carriers

used⁴¹ and particles prepared from highly pure lipids/carriers are usually more cuboid in nature^{42, 21}. PRO and CAR have high polydispersity indices (>0.8) in Table 1, showing they are chemically polydispersed as well as highly pure. Even though expected that only spherical particles would be present in all formulations, it should also be realized that the polymorphic nature of the carriers (data in brief) could determine the shape of particles. So that particles which existed in the stable β -modification could assume anisometric shapes, whereas those that existed in the metastable α -polymorphic forms could appear spherical in nature^{43, 44}. This agreed with literature as the particle shape making up the drug films could be spherical⁴⁵ and/or non-spherical²¹.

SEM images of the film surface and internal matrix are shown in Fig. 2 (A to O). The blank polymer films of CAR (images A-C) and PRO (images J-L) had uniform smooth appearance compared to the CARART (images D-F) and PROART (images G-I) films which in turn appeared uniform but slightly rough. However, with closer look into the internal structure, there appeared to be a higher, though irregular distribution of the ART within the film matrices (CARART) and (PROART). The internal structure of the PROART film (images G-I) showed more uniform distribution of irregularly shaped ART within the film matrix compared to CARART films (D-F) which had needle-like and/or rice-like particle clusters. This suggests that PROART film may have higher capacity for drug loading and retention, with fewer tendencies for drug expulsion to the film surface, than the CARART films. However, subsequent results would provide further proof on this.

Table 1: Properties of formulation

Batch	Z-Ave (d. nm)	PDI	ZP (mV)	Thickness (mm) $\pm$ SD	Bioadhesive activity (g/mm)	Equilibrium Water content (%)	Ex-Vivo Bucco Adhes. Strength $\pm$ SD	Melting peak ($^{\circ}$ C)	Enthalpy (J/g)
ART	-	-	-	-	-	1.70 $\pm$ 0.01	-	86.96	87.51
CARART	2442.0	1.00	-64.4	0.18 $\pm$ 0.02	23.76 $\pm$ 1.12	21.40 $\pm$ 0.08	38 $\pm$ 1.01	207.05	76.02
PROART	853.2	0.62	-10	0.28 $\pm$ 0.04	9.38 $\pm$ 0.58	15.02 $\pm$ 0.67	30 $\pm$ 1.21	186.25	21.63
CAR	568.50	0.80	-50.5	0.08 $\pm$ 0.01	19.24 $\pm$ 0.11	18.00 $\pm$ 0.06	25 $\pm$ 0.90	242.05	-3.16
PRO	798.9	0.92	-9.6	0.19 $\pm$ 0.01	17.24 $\pm$ 0.81	10.14 $\pm$ 0.06	21 $\pm$ 0.78	312.55	-0.79

Legends: Because the films had low water contents compared to pro-hydrogel state, the term equilibrium water content has been chosen.

Fig. 2: Morphology and internal structure of drug films and polymers.

Legends: Surface, internal structure and enlarged internal structure of k-carrageenan, CAR (A-C); drug film, CARART (D-F); drug film, PROART (G-I); *Prosopis africana* polymer, PRO (J-L) and drug, ART (M-O) respectively.

3.3. Microenvironment pH and particle characterization

The microenvironment of the films had the required pH within the range for saliva (6.5-6.9). This shows that the formulation would likely not irritate the buccal mucosa. Particle size characterization of the pure polymers (CAR and PRO) were 568.5 and 798.9 nm respectively whereas their

drug films (CARART and PROART) were 2442 and 853 nm respectively (Table 1). This implies that PROART films had better particle subdivision in the nanometer region than the CARART. This agrees with the observation in morphology and internal structure.

3.4. Technological evaluation of the films

The thickness of the blank films produced from pure polymers of PRO and CAR were 0.19 and 0.08 mm whereas their ART-loaded counterparts (PROART and CARART) were 0.28 and 0.18 mm respectively. These values were within normal ranges reported for drug films in literature⁴⁶. This shows that the PRO and/or PROART films were generally thicker than those of CAR and/or CARART.

3.5. Bioadhesive evaluation of the films

Bioadhesive determination revealed that work of adhesion varied depending on the polymer used. Table 1 generally shows that CARART films had higher work of adhesion (24 g/mm) than PROART films (9 g/mm), similar to the pure polymers (CAR, 19 and PRO, 17 g/mm).

3.6. Thermogravimetric analysis (TGA)

TGA result showed that water content within the films was dependent on the polymer used (Table 1). Films produced from CAR and/or CARART had higher equivalent water contents of 18 and 21 % respectively than those of PRO and/or PROART (10 and 15 %) respectively. The drug (ART) had a much lower equilibrium water content of 1.70 %, which agreed with an earlier study²¹.

3.7. Differential scanning calorimetry (DSC)

Enthalpy values of ART, CAR, PRO, CARART and PROART were 87.51, -3.16, -0.79, 76.02 and 21.63 J/g respectively (Table 1). This implies that the order of decreasing crystallinity was ART < CARART < PROART < CAR < PRO;

implying that the polymer (PRO) and the film (PROART) were the least crystalline. In other words, PRO was the most amorphous and its drug film (PROART) was also more amorphous than CARART; which by extrapolation implied that it was a better system to entrap the very crystalline ART, than CAR.

3.8. Infrared (FTIR) analysis

To demonstrate that it was possible to incorporate ART into polymers, infrared spectra of free ART, ART-loaded films (CARART and PROART) were obtained alongside individual polymers and presented. The bands at 3772, 3294, 2970, 2206, 1975, 1712, 1280, 1118 and 864 cm^{-1} were due to the vibration of the functional groups ($-\text{OH}$, $\text{C}-\text{H}$, CH_3 , $\text{C}=\text{O}$ and $=\text{C}-\text{H}$ out of plane bending vibration of aromatics & enes) present in the structure of ART and can be seen in the spectra of the free ART, CARART, and PROART films. Spectra from films containing no ART did not show these peaks, indicating successful incorporation of ART into the buccal film formulations. Briefly, the band 3200-3400 cm^{-1} as seen in CAR, more pronounced than in PRO represent normal 'polymeric' OH stretch, which can be broad stretching to 3570-3200 cm^{-1} in PRO. The OH stretching vibration (broad or not) were seen in the bands of 3400-3611 in CARAT; 3570-3200 cm^{-1} in PROART and 3570-3200 cm^{-1} (H-bonded OH group) in PRO. Other prominent points of interaction were at 1900 cm^{-1} between CARART and ART due to aromaticity. PROART and ART had more prominent points of interaction at 2400, 1650-1590 (primary amine NH bend from PRO) and 1680-1620 cm^{-1} due to aromaticity ($\text{C}=\text{C}$)³⁷.

Fig. 3: FTIR spectra

Legends: 3200-3400 cm^{-1} as seen in CAR, more pronounced than in PRO represent normal 'polymeric' OH stretch, it can be broad stretching to 3570-3200 cm^{-1} which is more pronounced in PRO. The OH stretching vibration (broad or not) can be seen in the bands of 3400-3611 in CARAT, 3570-3200 cm^{-1} in PROART and 3570-3200 cm^{-1} (H-bonded OH group). Other prominent points of interaction are at 1900 cm^{-1} between CARART and ART due to aromaticity. PROART and ART have more prominent points of interaction at 2400, 1650-1590 (primary amine NH bend from PRO) and 1680-1620 cm^{-1} due to aromaticity ($\text{C}=\text{C}$).

3.9. Dissolution studies

The dissolution experiment utilized two different media: deionized water and simulated salivary fluid (pH 6.5). It was observed that in deionized water, ART release from CARART films was 6.8 % after 4 h whereas PROART released 11.8 % of ART at the same time; whereas in SSF, ART release from CARART films was 8.89 % and PROART was 16.18 % at the same time. The high initial release of artemether observed in all the formulations may be caused by un-encapsulated drug

and a little burst release of artemether at the periphery of drug films. This perhaps, may be due to the fact that ART-loaded films of CARART and PROART generally had high particle sizes (2442 and 853 nm) respectively. Earlier works had highlighted that lower particle sizes increased drug release via increased surface area⁴⁷⁻⁴⁹. Therefore, since the drug films composed of high particle sizes, drug release was poor due to decreased surface area. More so, high polydispersity presents non-uniformity in release as different shapes and sizes of particles are involved.

Legend: Fast initial release was more pronounced in PROART than CARART but PROART release-curve was more sustained and preferable with less undulation (n=3).

Table 2: Kinetics of ART release from buccal films

Drug	Media	Batches	Zero order (R ²)	First order (R ²)	Higuchi (R ²)	Korsmeyer-Peppas Parameters (R ²)
ART	Deionized water	CARART	0.571	0.571	0.377	0.447
		PROART	-	-	-	-
	Simulated salivary fluid (SSF)	CARART	0.540	0.540	-	0.412
		PROART	-	-	0.377	-

Legends: R² values of the release models were generally low, perhaps due to complexity of the release whereas the theory of these kinetic models was based on simple defined release mechanisms and sometimes changing geometrics and structure of solid matrices. Hence, release of artemether could not be satisfactorily explained using the kinetic models

3.10. Antiplasmodial activity of films

The study showed a parasitemia reduction range of 146 – 48, 150 – 36 and 131 – 21 for CARART, PROART and ART (commercial oral tablet) respectively (Fig. 5). Therefore, mean parasitemia reduction was 67, 76 and 84 % for CARART, PROART films and ART respectively (Fig. 6). These

formulations had statistically significant ($P < 0.05$) antiplasmodial effects when compared to negative control group (S.D = 0.5) that received distilled water all through. The result equally confirmed that PROART had better antiplasmodial effect than CARART films, in agreement with all the earlier observations.

Legend: At day 1, the number of parasitized erythrocyte was nearly the same for all mice groups undergoing the treatment protocol. Subsequently at days 2-4, the number of parasitized erythrocyte continuously increased daily in the mice group that received deionized water. There was also a continuous pattern of decrease most prominently in ART (4.2), PROART (7.2) and CARART (9.6). The polymer (PRO and CAR) therefore, could serve as delivery carriers for artemether, as films for buccal use in malariogenic mice (n=3).

Legend: As shown earlier the mice that received water continuously increased in number of parasitized erythrocyte without any reduction. On the contrary, the drug (ART) and drug films (PROART and CARART) showed good percentage reduction of parasitaemia respectively as 86, 76 and 67 %. Though ART tablet performed best, yet it was used as oral tablet without taste-masking whereas, drug films were sweetened with saccharine sodium and flavoured with mint oil, which could additionally improve acceptability (n=3).

4. DISCUSSION

In the past and present, many companies utilize oral and intramuscular drug delivery technologies to develop artemether. Recent advancement pries into the delivery of drugs through buccal film formulation; hence in this study, sublingual administration has been chosen as a delivery route for possible systemic delivery of artemether.

Additionally, this approach is expected to improve patient compliance, since the extreme nausea-vomiting tendency of ART in the available conventional oral artemisinin combination therapies may be taken care of at once. The following results would provide proof as to hope for a sublingual ART regimen.

The particle uniformity of PROART films showed better polydispersity index (0.6) than CARART (1.0) as well as the single polymers of CAR (0.8) and PRO (0.9). Zeta potential values for CAR (-50.5 mV) and CARART (-64 mV) were better than those of PRO (-9.6 mV) and PROART (-10 mV). This suggests that the films (loaded with ART or not) based on CAR would be more stable than those of PRO. More so, the CAR and/or CARART films were more transparent than the PRO and/or PROART ones; hence suggesting that the CAR and/or CARART films were more plastic and would most likely require more time for breaking the films than those of PRO and/or PROART. Subsequently, the folding endurance of the PROART film was 43 min whereas that of CARART film was 60 min. This confirms that CARART films were lighter (more plastic) with more uniform measurement than PROART films. Additionally, CARART films would adhere more at mucosal surface to dissolve and release ART faster than PROART films. This agreed with both observations in thickness and folding endurance implying that CARART films adhered longer to the chicken pouch as a model tissue surface, than the PROART films. Since buccal films generally need to be bio- and/or muco-adhesive to be able to withstand some obvious stresses due to their application sites, in order to provide both local and/or systemic effects, it therefore follows that the CARART films were better adapted for bio-/muco-adhesion than the PROART films. This suggests that the flushing action of saliva and/or food ingestion would not affect CARART films as much as the PROART films; even though both may suffer from frequent dosing, non-uniform absorption as well as dislodgement by the tongue^{10, 32}. It was also observed that different films formulated with the same polymer had slight variation in water contents. Water molecules therefore, act as stabilizer to increase intermolecular spaces to allow polymeric chains to easily slide past each other⁵⁰. This however affects stability, drug release and other physicochemical properties (elastic modulus) of the films formulated as would be established from the thermal analysis.

DSC is a measurement tool that gives insight into the thermal properties of ingredients and formulations in terms of melting point, enthalpy and glass transition temperature^{18, 21, 51}. Summarily, high enthalpy values suggest high crystallinity of systems and vice versa. In other words, when a system has high enthalpy value, it is therefore rigid (crystalline) without enough space to entrap anything. This could also explain why the particle sizes of PRO and PROART films were in the nanoparticle subdivision rather than CARART; which by extension despite the low mucosal adhesivity of PROART films, could indicate that PROART films may have more sustained release of ART in SSF (pH 6.5) than CARART.

Information obtained from FTIR measurement gives insight into the kind of interaction occurring due to the functional groups making up the systems. Fig. 3 shows the spectra of all measurements. The compatibility among the ART, polymers (CAR and PRO) and films (CARART and PROART) was studied. However, some new peaks were formed in both PROART (2083 cm⁻¹) and CARART (3402, 2708, 2461, 2276, 2036, 1813-1936, 1211 and 694 cm⁻¹) due to intramolecular hydrogen bonding (O-H stretching vibration), aromatic, cyclic enes (ν=CH & Ar-H), alkyl groups (νCH₃), C=O groups (νC=O) and aromatics & enes (νC-H out of plane bending vibration). These studies confirm that, structural components of polymers (CAR and PRO) responsible for their less crystallinity (according to DSC result) and perhaps dissolution enhancement may play vital role in establishing various interactions with drugs and consequently stabilize them thermodynamically.

Many earlier reports carried out on stabilization using different polymers suggest the significance of hydrogen bonding in stabilization of amorphous valdecoxib using PVP and HPC⁵²; comparative study of stabilization efficiency of Gelucire 50/13 and PVP and investigation of mechanism involved⁵³; nanoporous silica xerogel, kaolin, and Mg-Al-hydrocalcite involved in stabilization of amorphous nifedipine⁵⁴, ibuprofen⁵⁵, and celecoxib⁵⁶ respectively. Polyvinyl pyrrolidone (PVP), hydroxypropyl cellulose (HPC), Gelucire and other carriers have been investigated to check their potential as stabilizer for amorphous form of drugs. PVP has been used to prevent devitrification of amorphous ketoconazole⁵⁷. The mechanism of this stabilization is also traceable in the use of PRO and CAR to deliver ART as buccal films in this study. Alternatively, PRO has been proven to be a stabilizer for aceclofenac in addition to many other uses²¹.

Release from CARART films followed a manner that was more controlled than PROART films, even though both release was poor (Figure not shown). On the other hand, ART release in SSF (pH 6.5) showed that CARART films achieved 11.76 % release in 2 h whereas PROART released 16.82 % in 2 h which was sustained till 10 h (Fig. 4). This suggests that for both fast and sustained release of ART, PROART films in SSF (pH 6.5) was the preferred formulation despite CARART films being more bioadhesive, stable (-64 mV), transparent (thinner) and more plastic. Meanwhile, ART (87.51 J/g) existed in more amorphous form in the PROART films (21.63 J/g) than CARART films (76.02 J/g); which therefore proves the enhanced dissolution and release of ART obtained from PROART films. Subsequently, the fine particle subdivision (853 nm) and double thickness advantage (0.28 mm) of PROART films as compared to the size (2442 nm) and thickness (0.18 mm) of CARART particles/films, could explain the sustained release of ART till the 10th hour. However, the *in vivo* antiparasitic activity would confirm these *in vitro* results. When the dissolution rate and pattern of the films were compared to the standard drug (pure ART), PROART in deionized water had dissolution pattern closer to it than CARART. The *in vitro* release was subjected to a kinetic analysis as shown in Table 2, for fitting into various models, such as zero-order, first-order, Higuchi, Hixson-Crowell and Peppas exponential equation to ascertain the drug release. The plots were found linear, though release of ART from the films did not fit into any of the kinetic models. The plots generally had low R² values. This behavior of the artemether films could be attributed to the complexity of the release, diffusion and permeation process, whereas the theory of these kinetic models was based on simple defined release mechanisms and sometimes changing geometrics and structure of solid matrices. Hence, release of artemether could not be satisfactorily explained using the kinetic models.

The result of *ex-vivo* buccoadhesive strength for ART buccal films are shown in Table 1. Thus CARART films containing carrageenan polymer exhibited higher buccoadhesive strength (38) than PROART film (32) containing *Prosopis africana* polymer. This may be due to surface adhesion phenomenon as well as formation of secondary hydrogen bonds with mucosa as a result of rapid swelling of polymers involved. The single entities of the polymers (CAR and PRO) demonstrated similar trends as well.

The therapeutic effect of CARART and PROART were tested on mice infected with *Plasmodium berghei* (NK 65). Reduction in parasite count was investigated by comparing mean parasitaemia pre- and post- treatment from the different film formulations. Mean parasitaemia reduction was 67, 76 and 84 % for CARART, PROART films and ART respectively. These formulations had statistically significant

($P < 0.05$) antiplasmodial effects when compared to negative control group (S.D = 0.5) that received distilled water all through. The result equally confirmed that PROART had better antiplasmodial effect than CARART films, in agreement with all the earlier observations such as fine particle subdivision (853 nm), double thickness advantage (0.28 mm) and sustained *in vitro* release of ART.

5. CONCLUSION

This study has demonstrated that natural polymers (CAR and PRO) can conveniently deliver ART as buccal films to treat malarial mice. The characteristics of the drug films more desirably favoured PROART than CARART films; hence better drug dissolution, release and antiplasmodial activity due to more uniform (0.6) amorphous (21.63 J/g) nanoparticles (853 nm) make-up of PROART films which thickly (0.28 mm), though porously and brittlely enclosed ART with lower equilibrium moisture content (15 %) for better stabilization (-10 mV) through intramolecular hydrogen bonding of the ART and PRO molecules; than CARART films with higher equilibrium water content (21 %) which increased intermolecular spaces allowing polymeric chains to easily slide past each other to expel entrapped ART. Overall, antiplasmodial efficacy was 86, 76 and 67 % corresponding to ART>PROART>CARART respectively. Since all formulations achieved reduction in parasitaemia between 67 and 86 %, nonetheless, the improved ease of application and compliance, perhaps with elimination of vomiting and other gastrointestinal disturbances associated with conventional ART, could create hope for a clinical trial since antiplasmodial efficacy of the formulations were statistically significant.
